ABSTRACT
Wind energy systems based on doubly fed induction generators (DFIGs) have been dominantly used in high-power applications since they use power-electronic converters with ratings less than the rating of the wind turbine generator. The DFIG is very sensitive to unbalanced grid voltage as its stator is directly connected to the grid. The rotor and stator currents could be highly unbalanced even under a very small unbalanced grid voltage. So there is much more importance of designing and modelling of controllers for eliminating the fault and sustaining fault ride through condition. Modelling of controllers is different for steady state condition and transient conditions with fault ride through conditions. This paper presents an overview of trends and advancements in control strategies of DFIG based wind turbine system in transient conditions.

Keywords
DFIG, control strategies, DPC, DTC, power quality, fault ride through, VC

1. INTRODUCTION
Wind energy, recognized as the main contribution to low carbon societies, has become one of the subjects of much recent research and development globally. Recently, more and more modern wind turbines are being installed in distribution and rural grids with low X/R ratios, and in developing countries, where the distribution grids are quite weak. As a result, the application of wind generation systems based on modern power electronics has promoted the development of new functionalities for wind turbines, i.e., voltage or frequency regulation, islanding operation, and uninterruptible operation under nonideal grid voltage conditions including symmetrical voltage dips, network unbalance, and harmonically distortions.

Among the various types of wind turbines, the variable speed wind turbines based on the doubly fed induction generator (DFIG), which have many advantages over the fixed speed induction generators or fully fed synchronous generators with full-sized converters, including variable-speed constant frequency (VSCF) operation, reduced flicker, independent control capabilities for active and reactive powers, and relatively lower converter cost and power losses, have attracted extraordinary attention by researchers and manufacturers all over the world.

Fig 1: Complete Wind Energy Conversion system
Fig.1 represents the complete wind energy conversion systems (WECS), which converts the energy present in the moving air (wind) to electric energy. The power developed by the wind turbine mainly depends on the wind speed, swept area of the turbine blade, density of the air, rotational speed of the turbine and the type of connected electric machine. As shown in Fig.1, there are primarily two ways to control the WECS. The first is the Aerodynamic power control at either the Wind Turbine blade or nacelle, and the second is the electric power control at an interconnected apparatus, e.g., the power electronics converters. The flexibility achieved by these two control options facilitates extracting maximum power from the wind during low wind speeds and reducing the mechanical stress on the wind turbine during high wind speeds.

The aerodynamic wind power control is essentially intended to control the input power of the wind turbine. There are three ways to perform aerodynamic power control.

1. Pitch Control: The blades are physically rotated around their longitudinal axis.
2. Stall Control: The angle of the blade is fixed, but the aerodynamic performance of the design is such that at high wind speeds the blades stall.
3. Yaw Control: In this technique the entire nacelle is rotated around the tower to yaw (oscillate around a vertical axis) the rotor out of the wind. Due to its complexity and susceptibility to stress, this technique is not commonly used.

Currently, Pitch Control is the most common method for aerodynamic control. Almost all variable speed wind turbine topologies (including the DFIG) use Pitch Control. At wind speeds below the rated speed, it is used to maximize the energy capture. At wind speeds above the rated speed, it is used to reduce the mechanical stress on the system.
Fig.2: DFIG controller topology

DFIG is an induction machine with a wound rotor, where the rotor and stator are both connected to electrical sources. The rotor is fed with a back to back converter the AC-DC-AC. This template allows converter used on the rotor which consists of two voltage sourced converters i.e., rotor side converter (RSC) and grid side converter (GSC), between the components a dc-link. Capacitor is placed as energy storage. In order to keep the voltage variations (or ripple) in the dc-link voltage small With the rotor side converter it is possible to control the torque or the speed of DFIG and also the power factor at the stator terminals. The main objective for the GSC is to keep the dc link voltage constant regardless of the direction of rotor power. The RSC works at different frequencies, depending on the wind speed

2. RSC CONTROLLER TOPOLOGY

The RSC applies the voltage to the rotor windings of the DFIG. The purpose of the RSC is to control the rotor currents such that the rotor flux position optimally oriented with respect to stator flux in order that the desired torque is developed at the shaft. The RSC uses a torque controller to regulate the wind turbine output power and the voltage (or reactive power) measured at the machine stator terminals. The power is controlled in order to follow a pre-defined turbine power-speed characteristic to track the maximum power point. The actual electrical output power from the generator terminals, added to the total power losses (mechanical and electrical) is compared with reference power which directly controls the system. Since the stator is connected to the utility grid and the influence of stator resistance is small, the stator magnetizing current $i_m$ can be considered as constant. Under voltage orientation the relationship between the torque and the $d$ axis voltages, currents and fluxes can be written as follows. The stator flux Equations are written in Eq. (4.2) neglecting leakage inductances:

$$\psi_{rd} = 0$$

$$\psi_{rq} = L_d i_{rq} + L_m i_{rq} = (L_d + L_m) i_{rq} + L_m i_{rq}$$

$$\approx L_m i_{rq}$$

(1)

The rotor voltage equation can be written by substituting the values of $\psi_{rd}$ and $\psi_{rq}$ as follows:

$$v_{rq} = R_i + \frac{di_{rq}}{dt} + \sigma L_r i_{rq} + (\sigma e - \omega_r) \sigma L_r i_{rd}$$

(2)

On solving the above equation can be re written as:

$$v_{rq} = R_i + \frac{di_{rq}}{dt} + \sigma L_r i_{rq} - (\sigma e - \omega_r) \sigma L_r i_{rd}$$

(3)

Similarly the simplified $d$-axis voltage is given by:

$$v_{rd} = R_i + \frac{di_{rd}}{dt} - (\sigma e - \omega_r) \sigma L_r i_{rq}$$

(4)

Fig.3: Vector Control Scheme for Rotor Side Converter

2.1 GSC Controller Topology

The GSC aims to regulate the voltage of the DC bus capacitor. Moreover, it is allowed to generate or absorb reactive power for voltage support requirements the function is realized with two control loops as well: an outer regulation loop consisting of a dc voltage regulator. The output of the dc voltage regulator is the reference current $I_{dc}^\text{ref}$ for the current regulator. The inner current regulation loop consists of a current regulator controlling the magnitude and phase of the voltage generated by

3. VARIOUS CONTROL STRATEGIES

Modelling and control of DFIGs have been widely investigated based on well-established vector control schemes in a stator field-oriented frame of reference. The vector control is a fast method for independent control of the real/ reactive power of a machine. Direct torque control (DTC) and direct power control schemes (DPC) have been presented as alternative methods which directly control machine flux and torque by selection of suitable vectors. In the following sections vector control, DTC and DPC are well explained for controlling of the grid side converter as well as rotor side converter the voltage and flux equations of a doubly fed induction machine are obtained from [5]

3.1 Vector Control Scheme

The standard voltage oriented vector control strategy is used for the machine side converter to implement control action. Here the real axis of the stator voltage is chosen as the $d$-axis [29]. The vector diagram is shown in Fig. 4.1. The mathematical modeling of the machine side converter is given in the following equations. Since the stator is connected to the utility grid and the influence of stator resistance is small, the stator magnetizing current $i_m$ can be considered as constant. Under voltage orientation the relationship between the torque and the $d$ axis voltages, currents and fluxes can be written as follows. The stator flux Equations are written in Eq. (4.2) neglecting leakage inductances:

$$\psi_{rd} = 0$$

$$\psi_{rq} = L_d i_{rq} + L_m i_{rq} = (L_d + L_m) i_{rq} + L_m i_{rq}$$

$$\approx L_m i_{rq}$$

(1)

The rotor voltage equation can be written by substituting the values of $\psi_{rd}$ and $\psi_{rq}$ as follows:

$$v_{rq} = R_i + \frac{di_{rq}}{dt} + \sigma L_r i_{rq} + (\sigma e - \omega_r) \sigma L_r i_{rd}$$

(2)

On solving the above equation can be re written as:

$$v_{rq} = R_i + \frac{di_{rq}}{dt} + \sigma L_r i_{rq} - (\sigma e - \omega_r) \sigma L_r i_{rd}$$

(3)

Similarly the simplified $d$-axis voltage is given by:

$$v_{rd} = R_i + \frac{di_{rd}}{dt} - (\sigma e - \omega_r) \sigma L_r i_{rq}$$

(4)
The unit vector is found in similar way as in the case of grid side converter. The reference value \( v_{rd*} \) and \( v_{dq*} \) which are being found from Eq. (3) and (4) are:

\[
V_{rd} = V_{rd} + i_{rd} R_r - (\omega - \omega_r) [i_{iq} L_r + i_{di} L_m] \tag{5}
\]

\[
V_{dq} = V_{dq} + i_{dq} R_r - (\omega - \omega_r) [i_{dl} L_r + i_{dl} L_m] \tag{6}
\]

Where \( v'_{rd} \) and \( v'_{dq} \) are found from the current errors processing through standard PI controllers. The reference current \( i_{d*} \) can be found either from the reference torque given by Eq. (9) or form the speed errors (for the purpose of speed control) through standard PI controllers. Similarly \( i_{q*} \) is found from the reactive power errors. The reactive power and speed is controlled using the current control loops.

The electromagnetic torque can be expressed as:

\[
\tau_e = \frac{3}{2} \frac{r}{\omega} (\psi_{rd} i_{dq} - \psi_{dq} i_{rd}) \tag{7}
\]

The value of \( i_{d*} \) found using eq. (7) is:

\[
i_{d*} = \frac{\psi_{sd}^*}{\psi_{sd}^*} \tag{8}
\]

And reference torque value is given by:

\[
\tau_e = \frac{3}{2} \frac{r}{\omega} (\psi_{sd}^* i_{dq} - \psi_{dq}^* i_{rd}) \tag{9}
\]

The plant for the current loop is decided by the line resistance and reactance, whereas dc link capacitor is taken as the plant for the voltage loop. The plants for the current loop and the voltage loop are given in Eq. (10) and (11) respectively are:

\[
F(s) = \frac{L}{\omega} \frac{\psi_{dq}(s)}{v_{dq}(s)} = \frac{L}{\omega} \frac{\psi_{dq}(s)}{v_{dq}(s)} = \frac{1}{\sigma L + R} \tag{10}
\]

\[
G(s) = \frac{3 P_{LM}}{4 L_s \psi_{dq}(j \omega + \beta)} = \frac{K}{(j \omega + \beta)} \tag{11}
\]

The main objective of the grid side converter is to maintain dc-link voltage constant for the necessary action. The voltage oriented vector control technique is approached to solve this issue. The control scheme utilizes current control loops for \( i_d \) and \( i_q \) with the \( i_d \) demand being derived from the dc-link voltage error through a standard PI controller. The \( i_q \) demand determines the displacement factor on the grid side of the choke. The \( i_d \) demand is set to zero to ensure unit power factor. The control design uses two loops, i.e. inner current loop and outer voltage loop to provide necessary control action. The plant for the current loop is decided by the line resistance and reactance, whereas dc link capacitor is taken as the plant for the voltage loop. The plants for the current loop and the voltage loop are given in Eq. (12) and (13) respectively are:

\[
F(s) = \frac{i_q(s)}{v_{dq}(s)} = \frac{i_q(s)}{v_{dq}(s)} = \frac{1}{L_s + R} \tag{12}
\]

\[
G(s) = \frac{v_{dq}(s)}{i_q(s)} = \frac{3 m_1}{2 V_{dc} L_s} \tag{13}
\]

Fig.4: Vector Control Scheme for Grid Side Converter

The active and reactive power is controlled independently using the vector control strategy. Aligning the d-axis of the reference frame along the stator voltage position is found by Eq. (14). \( V_{ds} = 0 \), since the amplitude of supply voltage is constant the active power and reactive power are controlled independently by means of \( i_d \) and \( i_q \) respectively following Eq. (15) are:

\[
\tan \theta_e = \frac{v_d}{v_q} \tag{14}
\]

\[
P_s = \frac{3}{2} (v_{d} i_d + v_{q} i_q) \tag{15}
\]

\[
Q_s = \frac{3}{2} (v_{d} i_q - v_{q} i_d) \tag{15}
\]

3.2 Direct Torque Control

The next generation of power control methods is direct torque control (DTC) [5, 6]. DTC decrease the use of machine parameters and reduces the complexity of vector control algorithms. The DTC method directly controls machine torque and flux by selecting voltage vectors from a look-up-table using the stator flux and torque information. One problem with the basic DTC scheme is that its performance deteriorates during starting and low-speed operations. Variable switching frequency and high torque ripple are the main limitations of hysteresis based DTC [33]. To address these limitations, DTC with space vector modulation based on synchronous reference frame transformation, predictive control and deadbeat control are reported here. A new DTC method where in rotor voltage vector is generated in polar form. Hence, the implementation of DTC using space vector modulation becomes simple compared to above mentioned methods. The method is also capable of independent control of torque and reactive power. The magnitude and angle of rotor voltage vector are controlled independently. The torque angle \( \theta_e \) is controlled in such a way that torque pulsations are reduced. To achieve this, a proportional-integral and resonant (PI+R) controller are used. The new DTC control method is a scalar control method, it does not require multiple reference frame transformation, sequential decomposition and notch filters to remove second harmonic components. The scheme of (PI+R) control in stationary frame is simple and complexity in calculations is significantly reduced.
chine parameters pertaining to $\delta_k$. More recently, DPC control of DFIG has significantly improved, especially under balanced grid voltage condition, the grid side converter (GSC) maintains the dc link voltage constant.

3.3 Direct power control

Based on the principles of DTC strategy, direct power control (DPC) was developed for three-phase pulse width modulation (PWM) rectifiers [16],[17]. From the previous research it has been shown that DPC is a more efficient approach compared to modified DTC [26],[27], [28]. The main drawback of the vector control system is that its performance depends greatly on accurate machine parameters pertaining to the stator, rotor resistances, and inductances. Thus, the performance degrades when the actual machine parameters depart from the values used in the control system. Direct power control (DPC) abandons the rotor current control philosophy, which is the characteristic of FOC. Also, DPC achieves bang-bang active and reactive power control by the modulation of the rotor voltage in accordance with the active and reactive power errors. DPC is characterized by its fast dynamic response, simple structure and robust response against parameter variations. Converter switching states were selected from an optimal switching table based on instantaneous errors of active and reactive powers and the angular position of converter terminal voltage vector [16],[17], or virtual flux that is the integration of the converter output voltage[18]. More recently, DPC control of DFIG-based wind turbine systems has been proposed. Based on the principles of DTC strategy, direct power control (DPC) was developed for three-phase pulse width modulation (PWM) rectifiers [19],[20], or virtual flux that is the integration of the converter output voltage [21]. More recently, DPC control of DFIG-based wind turbine systems has been proposed [22], [23]. In [22], the control system was based on the estimated rotor flux. Switching vectors were selected from the optimal switching table using the estimated rotor flux position, and the errors of the rotor flux and the active power/torque. The rotor flux reference was calculated using the reactive power/power factor reference. Since the rotor supply frequency, which equals the DFIG slip frequency, can become very low, rotor flux estimation is significantly affected by the machine parameter variations. In [23], a DPC strategy based on the estimated stator flux was proposed. Since the stator (network) voltage is relatively harmonic-free with fixed frequency, a DFIG’s estimated stator flux accuracy can be guaranteed. Switching vectors were selected from the optimal switching table using the estimated stator flux position, and the errors of the active power and reactive powers. Thus, the control system is very simple, and the machine parameters’ impact on system performance was found to be negligible. However a conventional DPC has switching frequency that varies significantly with active and reactive power variations, machine operating speed (rotor slip), and the power controllers’ hysteresis bandwidth [22],[23]. In [24], the method predicts the DFIG’s stator active and reactive power variations within a fixed sampling period, which is used to directly calculate the required rotor voltage to eliminate the power errors at the end of the following sampling period. This method directly controls the active power and the reactive power of the DFIG at

where, $K_K$ is the gain of resonant regulator, $a_k$ is the tuned resonant frequency, which is selected as, double the supply frequency. It may be noted that a low value of $K_K$ gives a very narrow frequency band. The block diagram for the implementation of proposed control scheme is shown in Fig. 4. Under unbalanced grid voltage condition, the grid side converter (GSC) maintains the dc link voltage constant.

Fig. 5: New Direct Torque Control method

Fig. 5 shows the schematic representation of new DTC method. The torque developed by DFIG is also given by:

\[ \tau_e = \frac{3}{2} p L_m \psi_s \psi_r \sin \delta \]  \hspace{1cm} (16)

Where \( L_m = L_s - \frac{L_2}{L_3} \) \hspace{1cm} (17)

And $\delta$ is the angle between stator flux vector and rotor flux vector. Under balanced condition, the reference torque and actual torque are steady (dc) quantities. Single PI regulator is required to process the error between reference torque and actual torque. The output of PI regulator generates the signal proportional to $(\Theta - \alpha)$. Under unbalanced grid voltage condition, the stator flux vector consists of double frequency component which results in the oscillation of torque at this frequency. To eliminate the torque oscillation, it is required to modulate the rotor flux vector by controlling $\delta$. Under unbalanced grid condition, the actual torque has an average dc value along with double frequency component. To process this double frequency fluctuating component of torque, the resonant regulator tuned at same frequency is used. PI regulator offers infinite gain for steady quantity, while resonant regulator offers an infinite gain at the selected resonant frequency. In addition, there is no phase shift and gain at other frequencies [36]. The block diagram of Proportional-integral and resonant (PI+R) controller is shown in Fig. 3. The output of PI regulator is a steady value of angle $(\Theta - \alpha)$ which corresponds to steady error between reference torque and average value of actual torque. The output of resonant regulator is a double frequency component of torque angle. As a result, the proposed PI+R controller forces the steady state errors to be null for both steady and double frequency components of torque. The open loop transfer function (OLTF) of PI+R regulator is as follows:

\[ \text{OLTF} = K_p + \frac{k_i}{s} + \frac{sK_r}{s^2 + \omega_0^2} \] \hspace{1cm} (19)

Fig 6: Block Diagram of Proportional Integral Resonant Controller

The output of resonant regulator is a double frequency component of torque angle. As a result, the proposed PI+R controller forces the steady state errors to be null for both steady and double frequency components of torque. The open loop transfer function (OLTF) of PI+R regulator is as follows:

\[ \text{OLTF} = K_p + \frac{k_i}{s} + \frac{sK_r}{s^2 + \omega_0^2} \] \hspace{1cm} (19)
constant switching frequency. Also, it has some privileges to the other DPCs; such as improvement of transient performance, negligible parameter effects on system performance and its good dynamic response. In this method the d-axis of the synchronous frame is fixed to the stator flux. As the stator is directly connected to the grid, and since the influence of the stator resistance can be neglected, the stator flux can be held constant. For a synchronous frame (the stator flux speed), the stator voltage vector is given as:

\[ v_{sd} = \omega_L \psi_{sd} \]  \hspace{1cm} (20)

In [5] the stator current is expressed as:

\[ I_{sdq} = \frac{l_m \psi_{s} - l_m \psi_{m} - l_m \psi_{sd}}{l_m} \]  \hspace{1cm} (21)

![Fig.7: Schematic diagram of DPC](image)

The stator active and reactive power inputs from the network can be calculated as:

\[ P_s = -k_r \omega_L \psi_{sd} \psi_{rd} \]  \hspace{1cm} (22)

\[ Q_s = k_r \omega_L \psi_{sd} (\frac{L_m}{l_m} \psi_{sd} - \psi_{rd}) \]  \hspace{1cm} (23)

\[ k_r = \frac{1.5 l_m}{\sigma L_s L_r} \]  \hspace{1cm} (24)

As the stator flux remains constant, according to (22) & (23) the active and reactive power changes over a constant period of Ts are given by:

\[ \Delta P_s = -k_r \omega_L \psi_{sd} \Delta \psi_{rd} \]  \hspace{1cm} (25)

\[ \Delta Q_s = -k_r \omega_L \psi_{sd} \Delta \psi_{rd} \]  \hspace{1cm} (26)

In the synchronous d-q reference frame, the rotor voltage is given by:

\[ v_{rd} = r_L i_{rd} + j \omega_L \psi_{rd} + \frac{d \psi_{rd}}{dt} \]  \hspace{1cm} (27)

\[ v_{rq} = r_L i_{rq} + j \omega_L \psi_{rq} + \frac{d \psi_{rq}}{dt} \]  \hspace{1cm} (28)

Combining equations (22) to (28) and neglecting the rotor resistance, the rotor voltage required to eliminate the power errors in the d-q reference frame is calculated as:

\[ v_{rd} = (K_P + \frac{K_I}{s}) (Q_s - Q_*) + \omega_s \frac{P_s}{k_r \psi_{sd}} \]  \hspace{1cm} (29)

\[ v_{rd} = \left( \frac{K_P}{s} + \frac{K_I}{s} \right) (P_s - P_*) + \omega_s \left( \frac{l_m}{L_m} \psi_{sd} - \frac{Q_s}{k_r \psi_{sd}} \right) \]  \hspace{1cm} (30)

A schematic diagram of the DPC for a DFIG system is shown in Fig.7. The controller contains two PI controllers, one for an active power and one for reactive power, as well as a SVM unit. The stator active and reactive powers can be calculated directly. The stator flux is estimated using the measured stator voltages and currents in the stationary reference. Considering equations (21) - (30), a block diagram displays the dynamics existing between \( P_s \) and \( V_s \) on the one hand, and between \( Q_s \) and \( V_s \) on the other hand. The overall control structure of a DPC is essentially constituted by one power controller. Fig. 4.6 shows that both dynamics are identical. Furthermore, this stator flux may be regarded as a constant disturbance whose effect on \( Q_s \) can be removed easily simply by closing the reactive power control-loop via a compensator that includes an integral action. It is fundamental to note that the error signals feeding the PI controller are computed by subtracting the set-point of the variable to be controlled, \( Q_s^* \) or \( P_s^* \), from its actual value, \( Q_s \) or \( P_s \), respectively. This is due to the fact that \( Q_s^* \) and \( Q_s \) are strictly negative. As a result, both \( Q_s \) and \( P_s \) closed-loop dynamics can be represented by the following unique second-order transfer function:

\[ \frac{P_s}{Q_s} = \frac{Q_s}{P_s} = \frac{k_r}{s^2} + \frac{k_p}{s} + k_i, \]  \hspace{1cm} (31)

From the transfer function (31), the dynamics are mainly influenced by constant \( kr \) values that are determined via the stator and rotor leakage and the mutual inductance. Substituting the stator and rotor inductances, the parameter \( kr \) is rewritten as follows:

\[ k_r = \frac{3}{2} \frac{1}{L_s L_r} \]  \hspace{1cm} (32)

![Fig.8: Overall Control System Of The DPC](image)

4. CONCLUSION

In this paper dynamic modelling of DFIG using vector control, direct torque control and direct power control are discussed. It has been shown that DPC is a more efficient approach compared to modified DTC and VC.
