ABSTRACT
An intention of MapReduce Sets for Chain Foldingexpressions analysis has to suggest criteria how Chain Foldingexpressions in Chain Folding data can be defined in a meaningful way and how they should be compared. Similitude based MapReduce Sets for Chain FoldingExpression Analysis and MapReduce Sets for Assignment is expected to adhere to fundamental principles of the scientific Chain Foldingprocess that are expressiveness of Chain Folding models and reproducibility of their Chain Foldinginference. Chain Foldingexpressions are assumed to be elements of a Chain Foldingexpression space or Conjecture class and Chain Folding data provide “information” which of these Chain Foldingexpressions should be used to interpret the Chain Folding data. An inference Chain Folding algorithm constructs the mapping between Chain Folding data and Chain Folding expressions, in particular by a Chain Foldingcost minimization process. Fluctuations in the Chain Folding data often limit the Chain Folding precision, which we can achieve to uniquely identify a single Chain Foldingexpression as interpretation of the Chain Folding data. We advocate an information theoretic perspective on Chain Foldingexpression analysis to resolve this dilemma where the tradeoff between Chain Foldinginformativeness of statistical inference Chain Folding and their Chain Foldingstability is mirrored in the information-theoretic Chain Foldingoptimum of high Chain Foldinginformation rate and zero communicationexpression error. The inference Chain Foldingalgorithm is considered as an outlier objectChain Foldingpath, which naturally limits the resolution of the Chain Foldingexpression space given the uncertainty of the Chain Folding data.

Keywords  
MapReduce, Chain Foldingexpressions, kernel function.

1. INTRODUCTION
The field of general expressionintention to formalize the notion of expressions in precise mathematical terms [1]. Expressions are perceived as regular structures behind the Chain Foldingdata sources, i.e., “the underlying deep regular structures are descriptions of the source, which are hidden via the sensing path” [3]. ExpressionIntention combines algebra, geometry and statistics to explain the nature of Chain Foldingdata sources and, thereby, depicts a generative Chain Foldingmodeling perspective on expression analysis. This philosophy argues for a distinct generative viewpoint to infer the probability distribution of the Chain Foldingdata.

In many real-world situations the Chain Folding data are represented or generated in a very high dimensional space and the information-processing task focuses on a low dimensional interpretation space. The analysis of visual Chain Folding data like images or videos provides a very convincing example of this situation: intensity expressions that are sensed by a camera are mathematically represented as points in a space with ℌ(#{pixels}) dimensions. When segmenting an image in semantically distinct regions then the interpretation space contains ℌ(#{pixels}) elements where the number of sites is often much smaller than the number of pixels. The reader should note that the space of segmentations is still exponentially large in the number of sites. Consequently, we adopt a discriminative view of MapReduce Sets for Chain FoldingExpression assignment: the Chain Foldingexpressions which are inferred from the Chain Folding data are elements of an interpretation space called Conjecture class and these Chain Foldingexpressions are more or less closely related with the Chain Folding data generating mechanism of the source. The Conjecture class often also reflects information about the aim of expression analysis, i.e., what the Chain Foldingexpressions are used for in subsequent information processing.

The inference of Chain Foldingexpressions in Chain Folding data is formulated as an algorithmic search for a stable subset of the underlying Conjecture class. Stability is required to guarantee that the Chain Foldingexpression analysis process would yield an equivalent outcome for the same structure of the Chain Folding data source but a different realization of the outlier object process. A second, antagonistic requirement of the Chain Foldingexpression analysis process is its specificity or informativeness: a small subset of the Conjecture class and in the limit a single Conjecture should be selected which poses a tradeoff to the stability requirement. Both Chain Folding principles mirror the reproducibility and specificity requirement of the scientific reasoning [9].

Chain Foldingexpression analysis algorithms often follow an optimization principle. Desired Chain Foldingexpressions are assigned a high score or low costs and undesirable Chain Foldingexpressions are discarded by assigning a low score or high costs. In the following, we adopt the terminology of cost minimization rather than score maximization. A kernel function defines a partial order of Conjectureminimal kernels distinguish where the most preferred Conjecture. The outlier object in the Chain Folding data, however, may introduce fluctuations in the kernels and the Conjecture with minimal kernels for one realization of the Chain Folding data may no longer minimize kernels for a second realization of the Chain Folding data. Therefore, we advocate stabilizing the set of kernel-minimal Conjecture by expanding it to a set of Conjecture with near-optimal kernels, also called approximation set. The size of such an approximation set is determined by information theoretic considerations.
Conjecture in the approximation set is considered to be statistically indistinguishable.

The intention of Conjecture does not depend on the measurements \( X_{\ell_1,\ldots,\ell_k} \) but potential Chain Foldingexpressions that are denoted by Conjecture are defined prior to any measurements. The reader should note that the notion of a “feasible solution” in applied mathematics and optimization often depends on constraints that are determined by measurements contrary to the intention in (2). Such situations can be modeled by unconstraint solution spaces with infinite kernels for those solutions that violate the constraints.

The Conjecture class for a MapReduce Set for Chain FoldingExpressionassignment problem is defined as the set of functions assigning an object or an object configuration (in the following, we restrict Conjecture to map an object to a Chain Foldingexpression. The more general situation of object configurations can be analyzed in an analogous way but involves a more complex notation) to an element of the Chain Foldingexpression space, i.e.,

\[
\mathcal{C}(\mathcal{O}) = \{ c(\mathcal{O}) : \mathcal{O} \in \mathcal{O} \}. \tag{3}
\]

A well-known example of a Conjecture class is the space of partitions or classification functions \( c : \mathcal{O} \rightarrow \{1, \ldots, k\} \), which we use in classification or clustering. When clustering \( n \) objects into \( k \) clusters, then we restrict the space of all possible partition functions to \( \mathcal{C}(\mathcal{O}) = \{1, \ldots, k\}^n \) for the object set \( \mathcal{O}^n \). The corresponding Conjecture class is denoted by \( \mathcal{C}(\mathcal{O}) = \mathcal{C}(\mathcal{O}^n) \). For parameter estimation problems the Chain Foldingexpressions are possible values of the matrices and the Chain Foldingexpression space is a subset of the \( d \)-dimensional Euclidean rotations.

### 2.2 Posteriori loss function approximation

The Conjecture class is a set of functions that map objects or object configurations to expressions. Chain Foldingexpression analysis requires assessing the quality of Conjecture \( c \in \mathcal{C} \). We adopt a kernel function viewpoint in this paper, which attributes a non-negative kernel value

\[
R : \mathcal{C}(\mathcal{O}) \times \mathcal{C}(\mathcal{O}) \rightarrow \mathbb{R}, \quad (c, X^{(n)}) \rightarrow R(c, X^{(n)}) \tag{4}
\]

each Conjecture given the measurements \( (\mathbb{R}, := [0, \infty]) \). Thenon-negativity assumption does not restrict the choice of kernel functions since we can always replace \( R(c, X^{(n)}) := R(c, X^{(n)}) - \inf c \Leftrightarrow R(c, X^{(n)}) \) for effectively computable minimal kernels.

The classical intention of statistical Inference [2] advocates to use the posteriori minimize as the solution of the inference problem. The best posterioriChain Foldingexpression denoted by \( c^+(X^{(n)}) \) minimizes the posteriori loss function of the Chain Foldingexpression analysis problem given the measurements \( X^{(n)} \), i.e.,

\[
c^+(X^{(n)}) \in \arg \min_{c \in \mathcal{C}} R(c, X^{(n)}). \tag{5}
\]

Although Conjecture map objects into a Chain Foldingexpression space, the posteriori loss function minimize \( c^+(X^{(n)}) \) depends on measurements.

The intention requires for inferability of classifications that the Conjecture class is not “too complex” (i.e., finite computing) and, as a consequence, the solution\( c^+(X^{(n)})\)converges to the optimal solution which minimizes the expected loss function. A corresponding criterion has been derived for regression [4].

This classical inference intention is not applicable when the size of the Conjecture class grows with the number of objects like in clustering or other optimization problems of...
combinatorial nature. Without strong regularization we cannot hope to identify a single solution, which globally minimizes the expected loss function in the asymptotic limit \( n \to \infty \). Conjecture class of combinatorial problems often have an infinite computing and, therefore, are not infeasible in the classical computing sense. Therefore, we replace the concept of a unique function as the solution of an inference problem with a weighted set of kernel functions. The challenge of inference then amounts to determine a weight measure, which is concentrated on few solutions to achieve precision. The weights were defined as functions which map triplets of a Conjecture, measurements and a resolution parameter to the unit interval, i.e.,

\[
w : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}_+ \to [0,1], \quad (c, X^{(n)}, \beta) \mapsto w_{\beta}(c, X^{(n)}). \tag{6}
\]

The set of weights is denoted as

\[
\mathcal{W} = \{ w_{\beta}(c, X^{(n)}): c \in \mathbb{R}^n \}.
\]

How should we choose the weights \( w_{\beta}(c, X^{(n)}) \) that large weights are only assigned to kernel functions with low kernels? The partial ordering constraint

\[
R(c, X^{(n)}) \leq R(\tilde{c}, X^{(n)}) \Leftrightarrow w_{\beta}(c, X^{(n)}) \geq w_{\beta}(\tilde{c}, X^{(n)}), \tag{7}
\]

ensures that kernel functions with minimal kernels \( R(\tilde{c}, X^{(n)}) \) assume the maximal weight value. Weights are normalized to one i.e., \( 0 \leq w_{\beta}(c, X^{(n)}) \leq 1 \). The non-negativity constraint of weights allows us to write the weights \( w_{\beta}(c, X^{(n)}) = \exp(-\beta f(R(c, X^{(n)}))) \) with the monotonic kernel function\( f(x) \). Since \( f(x) \) amounts to a monotone rescaling of the kernels \( R(c, X^{(n)}) \) we resort to the common choice of Statistical weights with the inverse computational value, i.e.,

\[
w_{\beta}(c, X^{(n)}) = \exp(-\beta R(c, X^{(n)})). \tag{8}
\]

It is worth mentioning that standard approximation sets as introduced in the intention of approximation algorithms would correspond to binary weights

\[
w_{\beta}^{\text{bin}}(c, X^{(n)}) \in \{ 0, \frac{1}{n} \} \text{ if } R(\hat{c}, X^{(n)}) \leq R(c, X^{(n)}) + \frac{1}{n} \beta \tag{9}
\]

The weight \( w_{\beta}(c, X^{(n)}) \) of a given Conjecture is a random variable of the measurements \( X^{(n)} \). We consider the quantity

\[
Z_{\beta}(X^{(n)}) := \sum_{i=1}^n w_{\beta}(c, X^{(n)}), \tag{10}
\]

which measures the total weight of Conjecture with low kernels. The weight sum is also known as the partition function in statistically when we use Statistical weights. In case of binary weights \( Z_{\beta}(X^{(n)}) \) denotes the number of solutions that are 1/\( \beta \) close to the optimum.

### 2.3 Generalization and the two instance scenario

To determine the optimal regularization of a MapReduce Sets for Chain FoldingExpressionassignment method we have to define and estimate the generalization performance of Conjecture. We adopt the two instance scenario with training and test Chain Folding data described by respective object sets\( \mathcal{O}' \), \( \mathcal{O} \) and corresponding measurements \( X, X' \sim \mathbb{P}(X) \). Both sets of measurements are drawn Independent and identically distributed from the same probability distribution \( \mathbb{P}(X) \). The training and test Chain Folding data\( X, X' \) define two optimization problems\( R(X), R'(X') \). The two instance scenario or two sample set scenario is widely used in statistics and statistical Inference.\cite{5}, i.e., to bound the deviation of posterior loss function from expected loss function, but also for two-terminal systems in information\cite{6,13}.

Statistical expression analysis requires that inferred Chain Folding expressions have to generalize from training Chain Folding data to test Chain Folding data since outlier object in the Chain Folding data might render the solutions\( c^{(X)} = c^{(X') \neq} \) unstable. How can we evaluate the generalization properties of solutions to a MapReduce Sets for Chain FoldingExpressionassignment problem? Before we can compute the kernels \( R(X, X') \) on test Chain Folding data of approximate solutions \( c(O') \in \mathbb{P}(O') \) on training Chain Folding data we have to identify a Chain Folding expression\( c(O') \in \mathbb{P}(O') \) which corresponds to \( c(O) \). A priori, it is not clear how to compare Chain Folding expressions \( c(O') \) for objects \( O' \) with Chain Folding expressions \( c(O) \) for objects \( O \). Therefore, we define a bijective mapping

\[
y : \mathbb{P}(O) \to \mathbb{P}(O'), \quad O' \mapsto y \circ O'. \tag{11}
\]

The mapping \( y \) allows us to identify a Chain FoldingExpressionConjecture for training set of objects \( c \in \mathbb{P}(O) \) with a Chain FoldingExpressionConjecture for a test set of objects \( c' \in \mathbb{P}(O') \). The reader should note that such a mapping \( y \) might change the object indices. In cases when the objects \( O', O \) are elements of an underlying metric space, then a natural choice for \( y \) is the nearest neighbor mapping.

The mapping \( y \) enables us to evaluate Chain FoldingExpression kernels on test Chain Folding data\( X' \) for Chain FoldingExpressionConjecture \( c(O') \) selected on the basis of training Chain Folding data\( X \). Consequently, we can determine how many training Chain Folding expressions with large weights share also large weights on test Chain Folding data, i.e.,

\[
\Delta Z_{\beta}(X, X') := \sum_{i=1}^n | w_{\beta}(c, y \circ X) - w_{\beta}(c, X') |. \tag{12}
\]

A large subset of Conjecture with jointly large weights indicates that low kernel Conjecture on training Chain Folding data\( X \) also perform with low kernels on test Chain Folding data. The tradeoff between stability and informativeness for Statistical weights on \( (8) \) is controlled by maximizing \( \beta \) for given loss function\( R(X, X) \) under the constraint of large weight overlap\( \Delta Z_{\beta}(X, X') / Z_{\beta}(X') \approx 1 \). A quantitative statement how close this ratio should approach unity requires a statistical decision intention as provided by information transmission.

### 2.4 Typicality of instances

A natural question in statistical inference arises from asymptotic considerations in the large \( n \)-limit. What is the asymptotic behavior of the log weight sum \( \log Z_{\beta}(X^{(n)}) \) dependent on the problem/instance size \( n \)? As remarked above the measurements\( X^{(n)} \) of a particular MapReduce Sets for Chain FoldingExpressionassignment instance depend on the value \( n \). In analogy to information\cite{7, 14} we assume that the log weight sum converge according to an asymptotic equipartition property, i.e.,

\[
\mathcal{F} := \lim_{n \to \infty} \frac{-\log Z_{\beta}(X^{(n)})}{\log |O^{(n)}|}, \tag{13}
\]

\[
\mathcal{F}' := \lim_{n \to \infty} \frac{-\log Z_{\beta}(X^{(n)})}{\log |O^{(n)}|}, \tag{14}
\]

\[
\Delta \mathcal{F} := \lim_{n \to \infty} \frac{-\log \Delta Z_{\beta}(X^{(n)}, X^{(n)})}{\log |O^{(n)}|}. \tag{15}
\]
path Expression suggests a. The approximately minimize a kernel function and the strings assigned to a specific problems. The weight distribution outlier object Hamiltonian distinguishable Random indistinguishable due to In the following, we describe an information theoretic INSTRUCTION 3.

\[ \log \left[ \mathcal{C} \left( O^{(n)} \right) \right] \]

These assumptions (13,14,15) requires that the log weight sums normalized by the size of the Conjecture class converge towards deterministic limits. The quantities \( F' \), \( F'' \) are known as the key values (up to a factor \( \beta' \)) for the instances \( R_{(\cdot,X)} \), \( R_{(\cdot,X')} \) in statistically. The factor \( \log \mathcal{C} \left( O^{(n)} \right) \) denotes the problem size of the optimization problem, i.e., it is \( O(n) \) for clustering problems with maximally \( k \) different partitions and \( O(\log(n)) \) for sorting problems with \( \log(n) = \log(n!n) \).

**Intention1.** The set \( A^{(a)} \) of jointly typical instances w.r.t. \( p(X^{(a)}) X^{(a)} = \) the set of instance pairs \( (X^{(a)}, X^{(a)} \in \mathcal{X}^{(a)} \times \mathcal{X}^{(a)} \) with posteriori log function partitions close to the respective key values

\[ A^{(a)} = \{ (X^{(a)}, X^{(a)}) \in \mathcal{X}^{(a)} \times \mathcal{X}^{(a)} : \left| \frac{-\log Z_{Y}(X^{(a)})}{\log \mathcal{C}(O^{(n)})} - \beta^{(a)} \right| < \epsilon, \ (16) \]

\[ \left| \frac{-\log Z_{Y}(X^{(a)})}{\log \mathcal{C}(O^{(n)})} - \beta^{(a)} \right| < \epsilon, \ (17) \]

\[ \left| \frac{-\log Z_{Y}(X^{(a)})}{\log \mathcal{C}(O^{(n)})} - \Delta \beta^{(a)} \right| < \epsilon \}. \ (18) \]

The reader should note that the weak law of large numbers guarantees convergence of posteriori entropies towards their expected values in information intention. Due to the dependence of the weights \( w(x^{(a)}, X^{(a)}) \) on the kernel function \( R_{(\cdot,X)} \) convergence has to be required for a kernel function. We also conjecture that kernel functions that violate this convergence behavior cannot be used to define predictive Chain Folding models.

![Fig 2: Generation of a set of M instruction problems by e.g. permuting the object indices.](image)

3. **DESCRIPTIVE STUDY I: INSTRUCTION BY APPROXIMATION**

In the following, we describe an information theoretic framework to determine which Conjecture are statistically indistinguishable due to outlier object in the measurements and how much we have to coarsen the Conjecture class. Randominstruction concept suggests a Chain Folding modelintention to determine the maximal number of distinguishable \( n \)-key value strings in the Group of Hamiltonian space when the key value strings are exposed to outlier object in a communication path. We develop a generalization of this idea for solution spaces of optimization problems. The weight distribution \( w(x^{(a)}, X^{(a)}) \) \( \mathcal{X}^{(a)} \) of the Conjecture class \( \mathcal{C} \) corresponds to the subsets of key value strings assigned to a specific instruction vector in information intention. Outlier object perturbs the measurements and therefore, the weight distribution fluctuates. An algorithm to approximately minimize a kernel function and the measurements as input to this algorithm defines an outlier objectpath in asymptotical communication scenario with a ChainMapper, a ChainReducer and a key generator \( K[G] [12] \). The key generator connects the ChainMapper with the ChainReducer by posing an optimization problem given a kernel function or an algorithm. Communication takes place by approximately optimizing a given kernel function, i.e., by calculating weight sets \( Z_{P}(X), Z_{P}(X') \). This instruction concept will be referred to as approximation set instruction (ASI) since the weights are concentrated on approximate minimizers of the optimization problem. The outlier objectpath is characterized by a Chain Foldingexpression kernel function \( R_{(\cdot,X)} \) that determines the path capacity of the ASI scenario. Selection and validation of MapReduce Sets for Chain FoldingExpressionassignment models are then achieved by maximizing the path capacity over a set of kernel functions \( R_{(\cdot,X)} \), \( \mathcal{O} \) where \( \theta \) indexes the various kernel functions or MapReduce Sets forChain FoldingExpressionassignment objectives. In a more general setting an arbitrary algorithm which does not necessarily minimize a kernel function can be considered to define a weight distribution and thereby, to play the role of a outlier objectpath [8] due to fluctuations in the input or in the execution path.

![Fig 3: Communication process: (1) the ChainMapper selects transformation \( \tau_{s} \) (2) the key generator draws \( X' \sim P(x) \) and applies \( \tau_{s} = \psi \circ \tau \circ \psi ' \) to it, and the ChainReducer estimates \( \hat{\tau} \) based on \( \tilde{X} = \tilde{\tau}_{s} \circ X' \).](image)

3.1 **InstructionChain Folding by transformations**

Before we describe the communication protocol we have to define the instruction for communication. We introduce random instructionintention to demonstrate the limits of asymptotical error free communication over an outlier objectpath. Random instruction refers to the fact that messages in randominstructionChain Folding model are selected as a set of key value strings \( \{ X^{(1)}, X^{(2)}, \ldots, X^{(n)} \} \) with length \( n = \log \mathcal{C}(O^{(n)}) \) that are drawn Independent and identically distributed according to a probability distribution \( p(\cdot) \). For sufficiently large \( n \), the instructions all have mutual variations which are highly concentrated around the expected variation \( 2np(1-p) \) with the probability \( p = P(\cdot) \) \( \mathcal{C}(1) = 1 \). In the asymptotic limit \( n \rightarrow \infty \), \( p \rightarrow 1/2 \), the random instructions uniformly partition the Group of Hamiltonian space of \( n \)-key value sequences into subsets of key value strings which can be reverse instruction without errors. In an analogous way, we can cover the Conjecture class by weight distributions [10]. To generate a uniform cover of the Conjecture class, we introduce a transformation

\[ \tau : \mathcal{O} \rightarrow \mathcal{O}, \mathcal{O} \rightarrow \eta, \mathcal{O}. \ (19) \]

The set of all possible transformations is denoted as \( \mathcal{T} \). Transformations that are restricted to object sets \( O^{(n)} \) of \( n \) objects are denoted by \( \tau^{(n)} \in T^{(n)} \). A random cover of the Conjecture class is then generated by selecting a set of transformations \( \{ \tau^{(n)} \in T^{(n)} : 1 \leq j \leq M, \tau^{(n)} \sim P(\tau^{(n)}) \} \) with a rate \( \rho := \log M / \log |T^{(n)}| \). A natural choice of the probability distribution for transformations is the uniform distribution \( P(\tau^{(n)}) = 1/|T^{(n)}| \). The intuition behind the transformations is
2. **Typicality of transformations**

Analogous to random instruction strategy, we generate the transformations $\mathcal{T}^{(o)}(c) := \mathcal{T}(\psi) \circ \mathcal{R}(\psi, X)$ in a random way. The probability distribution $P(t^{(o)})_{(t)}$ is defined over the set of possible transformations $\mathcal{T}^{(o)}$. An asymptotic equipartition property depends on the entropy density of the transformation set

$$\mathcal{H}(t) := \lim_{n \to \infty} \frac{\log P(t^{(o)})}{\log |\mathcal{T}^{(o)}|}.$$  

For instruction, we choose $\varepsilon$-typical transformations $t^{(o)} \in \mathcal{T}^{(o)}$ with the typical set $\mathcal{T}^{(o)}$ being defined in the following way:

**Intention 2.** The set $T^{(o)}$ of typical transformations w.r.t. $P(t^{(o)})_{(t)}$ is the set of transformations $t^{(o)} \in \mathcal{T}^{(o)}$ with the property

$$T^{(o)} := \{ t^{(o)} \in \mathcal{T}^{(o)} : \left| \frac{\log P(t^{(o)})_{(t)}}{\log |\mathcal{T}^{(o)}|} - \mathcal{H}(t) \right| < \varepsilon \}.$$  

Special cases of such transformations $t^{(o)}$ are random permutations when optimizing combinatorial optimization kernel functions like clustering Chain Folding models or graph cut problems. In parametric statistics, the transformations are parameter grids of e.g., rotations when estimating the orthogonal transformations of PCA or SVD.

### 3.3 Communication protocol

ChainMapper and ChainReducer agree on a kernel function for MapReduce Sets for Chain Folding Expression assignment $R(c, X)$ and on a mapping function $\psi$. The following procedure is then employed to generate the instruction for the communication process:

1. ChainMapper and ChainReducer obtain Chain Folding data $X$ from the key generator $\mathcal{B}_{\psi}$.
2. $\mathcal{B}_{\psi}$ calculates the weight set $\mathcal{B}_{\psi}(X)$.
3. $\mathcal{B}_{\psi}$ generates a set of (random) transformations $\mathcal{T} := \{ t_{1}, \ldots, t_{m} \}$. The transformations define a set of optimization problems $R(c, \tau \circ X)$, $1 \leq j \leq 2^{m}$ to determine weight sets $\mathcal{B}_{\psi}(\tau \circ X)$, $1 \leq j \leq 2^{m}$.
4. $\mathcal{B}_{\psi}$ sends the set of transformations $\mathcal{T}$ to $\mathcal{R}$ who determines the set of weight sets $\{ \mathcal{B}_{\psi}(\tau \circ X) \}_{\tau \in \mathcal{T}}$.

The reason behind this procedure is the following: Given the measurements $X$ the ChainMapper has randomly covered the Conjecture class $\mathcal{C}$ (O) by respective weight sets $\{ \mathcal{B}_{\psi}(\tau \circ X) : 1 \leq j \leq 2^{m} \}$, Communication can take place if the weight sets are stable under the stochastic fluctuations of the measurements. The criterion for reliable communication is defined by the ChainReducer to identify the transformation which has been selected by the ChainMapper. After this setup procedure, both ChainMapper and ChainReducer have a list of weight sets available.

How is the communication between ChainMapper and ChainReducer organized? During communication, the following steps take place as depicted in fig. 3:

1. ChainMapper selects a transformation $\tau_{s}$ message and sends it to the key generator $\mathcal{B}_{\psi}$.
2. $\mathcal{B}_{\psi}$ generates a new Chain Folding data set $X_{s}$ and establishes correspondence $\tau_{s}$ between $X$ and $X_{s}$. $\mathcal{B}_{\psi}$ then applies the selected transformation $\tau_{s}$, yielding $\hat{X} = \psi \circ \tau_{s} \circ X$.
3. $\mathcal{B}_{\psi}$ sends $\hat{X}$ to the ChainReducer without revealing $\tau_{s}$.
4. $\mathcal{B}_{\psi}$ calculates the weight set $\mathcal{B}_{\psi}(\hat{X})$.
5. $\mathcal{R}$ estimates the selected transformation $\tau_{s}$ by using reverse instruction rule

$$\hat{X} = \arg \max_{\tau \in \mathcal{T}} \sum_{c \in \Theta_{X_{s}}} \mathcal{B}_{\psi}(c \circ \tau \circ X) | c \circ \tau \circ X | w_{\beta}(c \circ \hat{X}).$$  

(22)

In the case of discrete Conjecture class, the communication path is bounded from above by the cardinality of $\mathcal{C}$ if two conditions hold: (i) the path is outlier object free $X_{s} \equiv X_{s}$; (ii) the transformation set is sufficiently rich that every Conjecture can be selected as a global minimizer of the kernel function.

### 4. PRESCRIPTIVE STUDY I: ERROR ANALYSIS OF APPROXIMATION SET INSTRUCTION

To determine the optimal approximation precision for an optimization problem $R(c, \psi)$ we have to derive necessary and sufficient conditions which have to hold in order to reliably identify the transformations, i.e., $\mathcal{R}$. The parameter $\beta$, which controls the concentration of weights and thereby the resolution of the Conjecture class, has to be adapted to the size of the transformation set $|\mathcal{T}|$. Therefore, we analyze the error probability of the reverse instruction rule (22) which is associated with a particular kernel function $R(c, \psi)$ a rate $\rho$. The maximal value of $\beta$ under the condition of zero error communication is defined as approximation capacity since it determines the approximation precision of the instruction scheme.

A communication error occurs if the ChainMapper selects $\tau_{s}$ and the ChainReducer reverses instead of $\tau_{s}$. To estimate the probability of this event, we introduce the weight overlaps

$$\Delta Z_{\beta} := \left| \mathcal{B}_{\psi}(\tau_{s} \circ X) - \mathcal{B}_{\psi}(\tau_{s} \circ X) \right|, \tau_{s} \in \mathcal{T}.$$  

(23)

The quantity $\Delta Z_{\beta}$ measures the number of Conjecture, which have jointly low kernels $R(c, \psi \circ \tau_{s} \circ X)$ and $R(c, \hat{X})$.

The probability of a communication error is given by a substantial overlap $\Delta Z_{\beta}$ induced by $\tau_{s} \in \mathcal{T} \setminus \tau_{s}$, $1 \leq j \leq M, j \neq s$, i.e.,

$$P(\hat{\tau} \neq \tau_{s}) = P(\max_{1 \leq j \leq M, j \neq s} \Delta Z_{\beta} \geq \Delta Z_{\beta}) \mid \tau_{s} \} \leq \Sigma_{1 \leq j \leq M, j \neq s} P(\Delta Z_{\beta} \geq \Delta Z_{\beta} \mid \tau_{s})$$  

(24)

The expectation $E_{\tau^{(s)}}$ is calculated w.r.t. the set of random transformations $\tau_{s}, 1 \leq j \leq M, j \neq s$, where we have conditioned on the ChainMapper selected transformation $\tau_{s}$. The joint probability distribution of all transformations $P(\mathcal{T}^{(s)}) = \prod_{\tau_{s} \in \mathcal{T}} P(\tau_{s})$ decomposes into product form since all transformations are randomly drawn from the set of all
possible transformations \( \{ \tau_j \} \). It corresponds to the randomization in Chain Folding in information intention.

The inequality (a) results from the union bound and (b) is due to Markov’s inequality. The identity (c) exploits the fact that the transformations \( \tau \in \mathcal{T} \) are independent and identically distributed drawn according to the measure \( \mathbb{P}(\mathcal{T}) \).

The expected overlap \( E_y \Delta Z_{\rho}^y / j \neq s \) with any other message \( \tau_j \), \( j \neq s \) for given training Chain Folding data \( X^a \) and test Chain Folding data \( X^c \) conditioned on \( \tau_j \) is defined by

\[
E_{y^a,s} \left[ (\Delta Z_{\rho}^y)(X^a, X^c) \right] = \Sigma_{y \in \mathcal{Y}} P(\tau_j)
\]

\[
\Sigma_{x \in \mathcal{X}} \omega_{\rho}(c, \psi \tau_j X) w_{\rho}(c, \tilde{X})
\]

\[
(\leq) \leq \Sigma_{x \in \mathcal{X}} \omega_{\rho}(c, \psi \tau_j X) \exp(\log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon))
\]

\[
\Sigma_{y \in \mathcal{Y}} P(\tau_j) \exp(\log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon))
\]

\[
\leq \exp(\log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) Z_{\rho}^y(X^a) Z_{\rho}^y(X^c)
\]

The inequality (d) results from the typically of \( P(\tau_j) \). The last inequality (e) holds since the set \( \{ \tau_j \} \) only adds positive terms. Effectively, the sum over a random transformation \( \tau_j \) decouples the two sums and yields a of weight sums. Inserting result (25) into equation (24) yields

\[
P(\tilde{\tau} \neq \tau_j | \tau_j) \leq (M-1) \exp(\log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon))
\]

\[
\prod_{x \in \mathcal{X}} Z_{\rho}^y(X) Z_{\rho}^y(X^c) / \Delta Z_{\rho}^y
\]

\[
(\leq) \leq \exp(\log M \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) - (\mathcal{F} - \epsilon) \log \mathbb{E}(\mathcal{O}^y)
\]

\[
- (\mathcal{F} - \epsilon) \log \mathbb{E}(\mathcal{O}^y) \Delta \mathcal{F} + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
\exp(\log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) - (\mathcal{F} - \epsilon) \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

\[
(\mathcal{F} - \epsilon) \mathcal{F} + \epsilon \log \mathbb{T}(\mathcal{T}|(\tau_j - \epsilon)) + \epsilon \log \mathbb{E}(\mathcal{O}^y)
\]

The term \( \log |Z_{\rho}^y| \) accounts the number of ways you can form statistically distinguishable subset of the complete transformation class \( \mathcal{T} \), the second term \( \log(|Z_{\rho}^y|) \) measures the same property on the ChainReduced side and the last term \( \log(|Z_{\rho}^y|) \) accounts for double counting of the last term. The three terms together define mutual information between the selected message \( \tau_j \) and the reconstructed message \( \tilde{\tau} \).

5. PRESCRIPTIVE STUDY II: INFORMATION THEORETICAL CHAIN FOLDING MODEL SELECTION

The analysis of the error probability suggests the following inference principle for controlling the appropriate strengths which implements a form of Chain Folding model selection: the approximation precision is controlled by \( \beta \) which has to be maximized to derive more precise solutions or Chain Folding expressions. For small \( \beta \) the rate \( \rho \) will be low since we resolve the space of solutions only in a coarse grained fashion. For too large \( \beta \) the error probability does not vanish which indicates confusions between \( \tau_j \) and \( \tilde{\tau} \). The optimal \( \beta \)-value is given by the largest \( \beta \)for, equivalently the highest approximation precision

\[
\beta^* = \arg \max_{\beta \in [0,\epsilon]} \mathbb{E}(\mathcal{T}|(\tau_j - \epsilon)
\]

Another choice to be made in modeling is to select a suitable kernel function \( R(y|x) \) for the MapReduce Sets for Chain Folding Expressions assignment problem set hand. Let us assume that a number of kernel functions \( \{ R_0(x|X), \theta \in \Theta \} \) are considered as candidates. The approximation capacity \( \beta \) depends on the kernel function through the weights. Therefore, we can rank the different Chain Folding models according to their \( \beta \) values. Robust and informative kernel functions yield a higher approximation capacity than simpler or more brittle Chain Folding models. A quantifiable choice is to select the kernel function

\[
R^*(c, X) = \arg \max_{\beta \in [0,\epsilon]} \mathbb{E}(\mathcal{T}|(\tau_j - \epsilon)
\]

Where both the random variables \( \tau_j \) and \( \epsilon \) depend on \( R_0(x|X), \theta \in \Theta \). The selection rule (32) prefers the Chain Folding model which is “expressive” enough to exhibit high information content (e.g., many clusters in clustering) and, at the same time robustly resists to outlier object in the Chain Folding data set. The key values, which are measured in the communication setting, are context sensitive since they refer to a Conjecture class \( \mathcal{O}^y(X) \), i.e., how finely or coarsely functions can be resolved in \( \mathcal{O}^y \).

6. DESCRIPTIVE STUDY II: MINIMIZING GROUP OF HAMILTONIANVARIATION

To demonstrate the approach to regularized optimization we will apply it to an almost trivial optimization problem, i.e., minimizing the Group of Hamiltonian variation to a reference key value string \( \xi \in \{ 1, 2, \ldots, n \} \in [-1, 1]^n \) of \( n \) key values. This optimization problem describes the reverse instruction step in classical communication intention. The kernel function for communication measures the difference between a key value string \( \xi \) and a reference instructiong\', i.e.,
The variable $s$ has to be optimized and the posteriori minimum is $s = \xi'$. However, $\xi$ is exposed to pathos like object and, in the spirit of approximation set instruction, we should only approximate it. The weights of approximate solutions are defined by

$$\mathcal{G}_\beta (\xi) = \{ w_\beta (s, \xi) = \exp ( - \frac{\beta}{2} (n - \sum_{i \in \Omega} s_i \xi_i) ) \}.$$ (34)

The ChainMapper uses this measurement $\xi'$ and permutes the key values according to one of the randomly selected transformations $\mathcal{F}_n := \{ \tau_1, \ldots, \tau_{2M} \}$. Permutations which leave $\xi'$ invariant are excluded. This set of randomly selected transformations generates an instruction with instruction vectors $\{ \tau_1 \circ \xi', \ldots, \tau_{2M} \circ \xi' \}$.

During communication, a second key value string $\xi''$ is generated by the key generator. The ChainReducer then receives the message $\xi = \tau \circ \xi'$ when the ChainMapper decides to communicate with transformation $\tau$. This process defines the approximation problem $R(s, \xi) = \frac{1}{2} (n - s \cdot \xi')$ on the ChainReducer side. Based on the Chain Folding data ChainReducer has to estimate the transformation $\tau$, which has been communicated by the ChainMapper.

Let us assume that the probability $\mathbb{P} (\xi' = \xi')$ characterizes the communication path. Therefore, a fraction $\delta$ of key values are different between the first key value sequence $\xi'$ and the second key value sequence $\xi''$, i.e., $\delta = \frac{1}{n} \{ i : \xi' \neq \xi'' \}$.  

The weight sums $Z_\beta (\xi), \xi \in \{ \xi', \xi'' \}$ are given by

$$Z_\beta (\xi) = \sum_{\xi'' \in \Omega} \exp ( - \frac{\beta}{2} (n - \sum_{i \in \Omega} s_i \xi_i) )$$

$$= \exp ( - \frac{\beta}{2} n \sum_{i \in \Omega} \exp ( \frac{\beta}{2} s_i \xi_i ) )$$

$$= \exp ( - \frac{\beta}{2} N \cdot (\cosh \beta)^{1/2} ).$$ (35)

The number of jointly approximating key value strings is determined by

$$\Delta Z_\beta = \sum_{\xi'' \in \Omega} \exp ( - \frac{\beta}{2} (n - \sum_{i \in \Omega} s_i (\xi' + \xi'')) )$$

$$= \exp ( - \beta \mu ) \Pi_{i \in \Omega} ( \exp ( \frac{\beta}{2} s_i (\xi' + \xi'')) )$$

$$= \exp ( - \beta \mu ) \cdot 2^{-n} (\cosh \beta)^{n (1 - \delta)}. $$ (36)

The mutual information (30) for the special case of minimizing Hamiltoianvariations is determined by

$$\mathcal{J}_\beta = I (\mu) + \mathcal{F}' + \mathcal{F}'' - \Delta \mathcal{F}$$

$$= \ln 2 - \lim_{n \to \infty} \frac{1}{n} (\ln Z_\beta (\xi') + \ln Z_\beta (\xi'')) - \ln \Delta Z_\beta$$

$$= (1 - \delta) \ln \cosh \beta - 2 \ln \cosh \frac{\beta}{2}$$

$$= \ln 2 + (1 - \delta) \ln \cosh \beta - \ln (\cosh \beta + 1). $$ (37)

where we have estimated the size of the set of possible random transformations as $| \mathcal{T} | = 2^n$. In the case of a biased sequence with $\pi := \mathbb{P}(\xi' = 1) \neq \frac{1}{2}$ the cardinality of the transformation set is $| \mathcal{T} | = 2^{n (2 - \delta)}$ with the binary entropy $H (\pi) = - \pi \ln_2 \pi - (1 - \pi) \ln_2 (1 - \pi)$.

The optimal value for $\beta$ determined by the maximum of $\mathcal{J}_\beta$, i.e.,

$$\frac{\partial \mathcal{J}_\beta}{\partial \beta} = (1 - \delta) \frac{\sinh \beta}{\cosh \beta} - \frac{\sinh \beta}{\cosh \beta + 1} = 0 . \quad (38)$$

$$\Rightarrow \cosh \beta = \frac{1 - \delta}{\delta} \cosh \beta + 1 = \delta^{-1} . \quad (39)$$

Inserting these values into equation (37) yields

$$\mathcal{J}_\beta = \ln 2 + (1 - \delta) \ln \frac{1 - \delta}{\delta} - \ln \frac{1 - \delta}{\delta} - \ln \frac{1}{\delta}$$

$$= \ln 2 - \delta$$.

Equation (40) shows that optimally approximating the Group of Hamiltonianvariation of key value strings by approximation set instruction yields the path capacity of the binary symmetric path with key value error probability $\delta$.

7. CONCLUSION

MapReduce Sets for Chain Folding expression analysis explores the questions how similar different Chain Folding expressions are and how we should compare them. The underlying topology and metric of a Conjecture class are often chosen ad hoc in applications and usually do not derive from properties of the Chain Folding data source. Approximation set instruction as a Chain Folding model validation principle establishes a notion of Chain Folding expression equivalence by considering them as statistically indistinguishable when the Chain Folding expression differences cannot be exploited for instruction. Chain Folding expressions with the same or similar weights are considered to be equally acceptable solutions and these weights directly depend on the objective or kernel function. To justify a natural topology and metric, we have to validate the underlying kernel function for the Chain Folding expression analysis problem. The reader should realize that the assumption of a kernel function assumes a lot of information about the Conjecture class; it essentially establishes a partial order of Conjecture.

Chain Folding model selection and validation requires estimating the generalization ability of Chain Folding models from training to test Chain Folding data. "Good"Chain Folding models show a high expressiveness and they are robust w.r.t. outlier object in the Chain Folding data. This tradeoff between informativeness and robustness ranks different Chain Folding models when they are assessed on new Chain Folding data and it quantitatively describes the underlying/overfitting dilemma. In this paper we have explored the idea to use approximation sets of clustering solutions as a communication instruction. The approximation capacity of a kernel function provides a selection criterion, which renders various Chain Folding models comparable in terms of their respective key value rates. The number of reliably extractable key values of a Chain Folding expression analysis kernel function $R (X \xi)$ defines a "task sensitive information measure" since it only accounts for the fluctuations in the Chain Folding data $X$ which actually have an
influence on identifying an individual Chain Folding expression or a set of Chain Folding expressions.

The maximum entropy inference principle suggests that we should average over the statistically indistinguishable solutions in the optimal approximation set. Such a Chain Folding model averaging strategy replaces the original kernel function with the value and, thereby, it defines a continuation method with maximal robustness. Algorithmically, maximum entropy inference can be implemented by annealing methods. The entropy naturally answers the question in many Chain Folding data analysis applications, which regularization term should be used without introducing an unwanted bias. The second question, how the regularization parameter should be selected, is also answered by: Choose the parameter value that maximizes the approximation capacity! The link to robust optimization is analyzed from a theoretical computer science viewpoint.

For Chain Folding model selection can be applied to all combinatorial or continuous optimization problems, which depend on outlier object Chain Folding data. The outlier object level is characterized by two sample sets: X, X′. It has been posteriorly explored by Chain Folding model validation problems for Chain Folding model based clustering of high dimensional Gaussian distributed Chain Folding data and of Boolean Chain Folding data. The well-known spin glass phase of maximum likelihood estimations for Gaussian sources is identified as structure with zero information content for instruction. IT can also be used to select Chain Folding models for spectral clustering. Furthermore, denoising of Boolean matrices guided by the generalization capacity of SVD suggests a cutoff rank for the SVD spectrum [11].

The reader should realize that we only require an objective or kernel R(.|X) to define a weight distribution. Any other mechanism to arrive at such a concept of approximate solutions will serve the same purpose. In principle, this concept of measuring the generalization performance of algorithms can be applied to algorithm evaluation and also to robust algorithm Chain Folding. It endows the space of algorithm with a topology since two algorithms are neighbors if their approximation sets for the same input distributions share a high overlap. Such methods to measure the robustness of algorithms to errors in the computation or in the input will be in high demand to program novel hardware that trades consumption against precision of computation. So far we are completely lacking Chain Folding principles for algorithm engineering, which consider this tradeoff between usage and correctness. We are also convinced that the information theoretic analysis of algorithms will shed new light on the relation between computational complexity and statistical complexity – the two faces of complexity science whose relation is far from being understood.
